Carbon nanotubes–properties and applications: a review

Khalid Saeed Ibrahim*

Department of Chemistry, University of Malakand, Khyber Pakhtunkhwa, Pakistan

Abstract

The carbon nanotube (CNT) represents one of the most unique inventions in the field of nanotechnology. CNTs have been studied closely over the last two decades by many researchers around the world due to their great potential in different fields. CNTs are rolled graphene with SP² hybridization. The important aspects of CNTs are their light weight, small size with a high aspect ratio, good tensile strength, and good conducting characteristics, which make them useful as fillers in different materials such as polymers, metallic surfaces and ceramics. CNTs also have potential applications in the field of nanotechnology, nanomedicine, transistors, actuators, sensors, membranes, and capacitors. There are various techniques which can be used for the synthesis of CNTs. These include the arc-discharge method, chemical vaporize deposition (CVD), the laser ablation method, and the sol gel method. CNTs can be single-walled, double-walled and multi-walled. CNTs have unique mechanical, electrical and optical properties, all of which have been extensively studied. The present review is focused on the synthesis, functionalization, properties and applications of CNTs. The toxic effect of CNTs is also presented in a summarized form.

Key words: carbon nanotube, synthesis, functionalization, toxic effect of CNTs

1. Introduction

In recent years, much research has focused on nanotechnology and nanocomposites. Researchers select specific filler and introduce it into a specific polymer to achieve a specific composite with modified properties. If the filler is a nano material, the composite is termed a nanocomposite [1]. Nanotechnology brings evolutionary changes to everyday life.

1.1 Nanotechnology

The word “nano” is from the Greek, meaning dwarf (small); scientific treatment at the nano level (atomic level) with the help of special scientific instruments is known as nanotechnology, which has become a well-known field in the last three decades [2]. The word “nanotechnology” was coined by Norio Taniguchi in 1974, in Japan. He stated that, “nanotechnology mainly consists of the processing steps of the separation, consolidation and deformation of materials by one atom or one molecule [3]. Nanotechnology is a vast field which explores many facts about the structures and properties of materials.

1.2 Carbon nanotubes (CNTs)

CNTs, also called buckytubes, are cylindrical carbon molecules with unique properties that make them potentially useful in a wide variety of applications. These include applications in nano-electronics, optics, and materials applications. CNTs exhibit extraordinary strength as well as unique electrical, mechanical and thermal properties. CNTs are the members of the fullerene family, which was discovered by Kroto et al. [4] in 1985. Buckyballs are spherical fullerenes, whereas CNTs are cylindrical, with at least one end typically capped with a...
1.4.1. Single-walled CNTs

Single-walled CNTs (SWCNTs) are made of a single graphene sheet rolled upon itself with a diameter of 1–2 nm (Fig. 2). The length can vary depending on the preparation methods.

1.4.2. Double-walled CNTs

These nanotubes are made of two concentric carbon nanotubes in which the outer tube encloses the inner tube, as shown in Fig. 3.

1.4.3. Multi-walled CNTs

MWNTs consist of multiple layers of graphene rolled upon itself with diameters ranging from 2 to 50 nm depending on the number of graphene tubes. These tubes have an approximate inter-layer distance of 0.34 nm [13].
2. Synthesis of CNTs

CNTs can be prepared by various methods, such as the arc-discharge method, chemical vapor deposition (CVD), and laser ablation.

2.1. Arc-discharge method

In 1991, Iijima [5] reported the existence of a new tabular-shaped species, now called CNTs. The tubes were produced using an arc-discharge evaporation method similar to that used for fullerene synthesis in the past. Carbon needles with diameters ranging from 4 to 30 nm and lengths up to 1 mm were grown on the negative end (cathode) of a carbon electrode by means of the direct current (DC) arc-discharge evaporation of carbon in an argon-filled vessel (100 torr). Ebbesen and Ajayan [17] reported the large-scale synthesis of MWNTs by this method.

The arc-discharge assembly includes two vertical thin electrodes installed in the center of the chamber. The lower electrode (cathode) has a shallow dip to hold a small piece of iron during the evaporation phase. The arc-discharge can be generated by running a DC current of 200 A at 20 V between the two electrodes. The use of the three components, argon, iron and methane, is critical for the synthesis of SWNTs. In the arc-discharge synthesis of nanotubes, Bethune et al. [18] used as anodes thin electrodes with bored holes which were filled with a mixture of pure powdered metals (Fe, Ni or Co) and graphite. The electrodes were vaporized with a relatively low current of 95–105 A at 100–500 Torr in a He atmosphere. Large quantities of CNTs were generated using this technique by Journet et al. [19]. The arc was generated between two graphite electrodes in a reactor under a helium atmosphere (660 mbar).

2.2. Laser ablation

In 1996, Thess et al. [20] reduced high yields (>70%) of CNTs by means of the laser ablation of graphite rods with small amounts of Ni and Co at 1,200°C.

In this method, the graphite target is bombarded with laser light. The tube grows until too many catalyst atoms aggregate on the end of the nanotube. The large particles either detach or become over-coated with sufficient amounts of carbon to poison the catalysis. This allows the tube to terminate with a fullerene-like tip or with a catalyst particle.

2.3. Chemical vapor deposition

In the above synthetic techniques, two major problems remain, i.e., the realization of both large-scale production and ordered synthesis [21]. However, in 1996, a CVD was discovered for nanotube synthesis [22,23]. This method is capable of controlling the growth direction on the substrate and synthesizing a large quantity of nanotubes [22]. During this process, a mixture of hydrocarbon gas, acetylene, methane or ethylene and nitrogen is introduced into the reaction chamber. During the reaction, nanotubes are formed on the substrate by the decomposition of the hydrocarbon at temperatures 700°C–900°C at atmospheric pressure [23]. This technique has two major benefits. The nanotubes are obtained at a much lower temperature, although at a lower quality, and the catalyst can be deposited over the substrate, which allows CNTs to adopt well-organized structures.

2.4. Vapor-phase growth

This is a relatively new technique and a modified form of CVD. The main difference is that the CNTs are synthesized directly from the reaction gas and catalytic metal in the chamber without a substrate [24]. Two furnaces are placed inside the reaction chamber. The catalyst used in this case is ferrocene. Vaporization of catalytic carbon is maintained at a relatively low temperature in the first furnace. Fine catalytic particles are formed here and when they reach the second furnace, and the decomposed carbons are absorbed in this catalyst by diffusion, where they are converted into CNTs.

2.5. Flame synthesis method

Another method by which CNTs can be prepared is the flame synthesis method. In this method, hydrocarbon flames are utilized. These flames assist with the initiation and growth of CNTs. Gases such as CO, CH₄, C₂H₂, C₂H₆, and C3H₈, which are present in the post-flame area, are rich sources of carbon. The reaction is exothermic and chemical energy released in the form of heat in the flame supports endothermic carbon deposition reactions. Catalysts are also required to provide reaction sites for the deposition of solid black carbon. CNTs grow in the same manner as in CVD. If an appropriate catalyst and flame and reaction conditions are provided, large amounts of CNTs can be gained commercially [25].
2.6. Recent trends in the synthesis of CNTs

A recent nebulized spray pyrolysis method has also been used for the synthesis of MWNTs. A nebulized spray, the key factor in this method, is generated by a special ultrasonic atomizer. MWNTs with fairly uniform diameters in aligned bundles have been obtained via this technique. Using an ultrasonic nebulizer, ferrocene (catalyst) and ethanol (as solvent and carbon source) are sprayed into a tubular furnace at a fixed temperature of 800°C under an argon flow of 1 L/min. Ethanol is used as a solvent as well as a carbon source due to its non-polluting nature, low cost, harmless byproducts (e.g., CO), and ease of handling. High growth of MWNTs on a surface can be produced. The advantage of using a nebulized spray is the ease of scaling into an industrial-scale process, as the reactants are fed into the furnace continuously [26].

3. Properties

CNTs reportedly have extremely high surface areas, large aspect ratios, and remarkably high mechanical strength. The tensile strength of CNTs is 100 times greater than that of steel, and the electrical and thermal conductivities approach those of copper [27,28]. These unique properties make CNTs good candidates as fillers in different polymers and ceramics to realize desirable consumer products [29,30]. It has also been predicted that CNT-based field-effect transistors (FETs) will soon supplant their silicon-based analog counterparts [31]. CNTs are also good incorporating agents due to their unique electrical, mechanical and thermal properties.

3.1. Electronic nature of CNTs

CNTs show electrical properties in chiral forms. Researchers have demonstrated that CNTs exhibit unique conductive properties. These results were the first to suggest that geometric differences such as defects, chirality, different diameters and the degree of crystallinity of the tubular structure greatly influence the electronic properties of CNTs [32,33]. SWNTs are metals with resistivities that range from 0.34 × 10^4 to 1.0 × 10^4 ohm·cm [27]. Considering the bonding of the carbon atoms in CNTs, arranged in a hexagonal lattice, each carbon atom is covalently bonded to three neighbor carbons via sp^2 molecular orbitals. Thus, the fourth valence electron remains free in each unit, and these free electrons are delocalized over all atoms and contribute to the electrical nature of CNTs. Thus, CNTs can be conducting or semi-conducting types depending on the type of chirality [25-37] Semiconducting SWNTs are usually in the form of p-type semiconductors [38]. MWNTs are composed of many tubes of SWNTs and therefore are not likely to be strictly one-dimensional conductors. A pseudo-gap was observed in I–V measurements, which attributes to its conducting nature [39].

From the above discussion, we note that the electrical properties of both SWNTs and MWNTs have been relatively well explored. This area has been a field of great interest since the last decade [40,41]. SWNTs, due to the ballistic nature of electron transport, can be described as quantum wires. On the other hand, transport in MWNTs is found to be fairly diffusive or quasi-ballistic [42]. CNTs, due to their electronic nature, can be used in transistors and other switching applications in advanced electronics [43]. The most recent application of nanotubes was an emitter. The important aspect of CNT emitters is that the emission can be obtained at a lower threshold voltage [44]. CNTs can also be used in sensors, micron-scale on-chip triodes at a high frequency (~200 MHz), vacuum microelectronics, and for X-ray generation [45,46].

3.2. Mechanical properties of CNTs

CNTs are considered as the strongest materials in nature at this point. The literature suggests that CNTs are very strong materials, especially in the axial direction [47]. The Young’s modulus ranges from 270 to 950 GPa, while the tensile strength is also very high, in the range of 11–63 GPa. Several reports have shown that in the radial direction, CNTs are rather soft [48]. The first TEM observation of radial elasticity showed that Vander Waal’s forces can deform two adjacent nanotubes [49]. Later, nano-indentations with an atomic force microscope (AFM) were performed by different groups of researchers to measure the radial elasticity of MWNTs quantitatively, and tapping/contact mode AFM was recently used to examine SWNTs [50-52]. The results showed that CNTs are in fact very soft in the radial direction. The radial direction elasticity of CNTs is important, especially for the formation of CNT nanocomposites and their mechanical properties, in which embedded tubes are subjected to large deformation in the transverse direction when a load is applied to a composite structure. Because the carbon-carbon bonds observed in graphite are among the strongest in nature, CNTs have excellent potential as they are the stiffest and toughest structure ever synthesized by scientists. Studying CNTs under TEM has shown that these materials are flexible and do not break upon bending [53-57]. Earlier theoretical calculations were carried out to predict the mechanical properties of CNTs [58-60]. The first attempt to determine the Young’s modulus for individual MWNTs was performed by Treacy et al. [28], who measured the amplitudes of thermal vibrations in CNTs under TEM. They demonstrated that nanotubes possess an average Young’s modulus of Y = 1–1.8 TPa, which is extremely high compared to commercially available carbon fibers (Y ≥ 800 GPa). Various research groups performed direct measurements of the bending forces of MWNTs as a function of the displacement inside an AFM. The values for the Young’s modulus were found to be between 0.32 and 1.47 TPa [61-70]. Falvo et al. [61] observed that MWNTs could be bent at sharp angles without undergoing any structural fracturing using an AFM tip. Endo et al. [62] observed that while breaking vapor-grown CNTs in liquid nitrogen, an inner tubule could survive this pressure. Zhu et al. [63] applied high pressures (50 GPa) at room temperature, using shock waves, to arc-discharge MWNTs and noted that the tubes do not break but collapse; that is, the outer shells transform into curled graphene domains while the inner cores display structural defects. More theoretical work on the mechanical properties of CNTs was carried out by Sinnott et al. [70], who found that SWNTs could exhibit a Young’s modulus as high as that of diamond. Yakobson [71] and Ru [72] proposed a mechanism of CNT transformation under uniaxial tension, leading to pentagon-heptagon defects in...
these tubes under high stress. Guanghua et al. [73] also showed theoretically that the mechanical properties of SWNTs are mainly dependent on the diameter. They estimated the theoretical Young’s modulus of nanotubes, of ≈1 nm diameter, is in the range of 0.6–0.7 TPa. Hernandez et al. [74] also obtained theoretical values of the Young’s modulus which were in close agreement with those obtained experimentally for MWNTs (1–1.2 TPa). They also reported that the increase in diameter is proportional to the enhancement of the mechanical properties and that if the diameter is increased to a certain value, the Young’s moduli of the tubes approach those of planar graphite.

Yu et al. [47,50] measured the Young’s modulus of individual SWNTs, reporting values between 320 and 1470 GPa and determining a breaking strength of SWNTs on the perimeter of each rope ranging from 13 to 52 GPa.

3.3. Thermal properties of CNTs

As rolled graphitic structures, CNTs are of great importance and interest not only for their electronic and mechanical properties, but also for their thermal properties. Although their size is very small, the quantum effects are important and the low-temperature specific heat and thermal conductivity show direct evidence of the 1-D quantization of the phonon band structure in CNTs [56,70,75]. The incorporation of pristine and functionalized nanotubes to different materials can double the thermal conductivity for a loading of only 1%, showing that nanotube composite materials may be useful for thermal management applications in industries. Kim et al. [76] measured the thermal conductivity of individual MWNTs and found it to be 3,000 W/K (higher than that of graphite) at room temperature. Beside this they also determined that the value is two orders higher than the magnitude those obtained for bulk MWNTs. A similar study was carried for SWNTs, with this result being greater than 200 W/m K for SWNTs [77]. There are several factors which influence the thermal properties such as the number of phonon-active modes, the length of the free path for the phonons, and boundary surface scattering [77-79]. These properties also depend on the atomic arrangement, the diameter and length of the tubes, the number of structural defects and the morphology, as well as the presence of impurities in the CNTs [80-82].

4. Dispersion of CNTs

One of the problems associated with CNTs is the agglomeration of these tubes due to weaker intermolecular forces, leading to difficulty in their dispersion in different polymeric mediums and even in various solvents. The functionalization of CNTs is carried out to overcome their agglomeration and bundle formation, which also enhances their dispersion in polymeric materials and solvents. Thus, the purification or functionalization of CNTs is very important to enhance their degrees of reactivity and homogenous dispersion. Purification removes unwanted particles that remain after the synthesis process, while functionalization introduces a specific functional group onto the side chains or ends of the CNTs [83]. Different methods are used by researchers for the functionalization and dispersion of CNTs. These include the following:

4.1. Non-covalent functionalization

This type of functionalization is based on Van der Waal’s forces. Beside these forces, hydrophobic or Pi-Pi interactions have also been reported. Non-covalent functionalization is important and interesting because it does not damage or modify the CNTs structure to a great extent. In solution beside van-der Waal’s forces some other forces are also involved, which render the efficiency of this type of functionalization. Some common examples of this type of functionalization include use of surfactant, especially with SWNTs, CNT wrapping, and non-covalent protein interactions [84].

4.2. Covalent functionalization

In this type of functionalization, the desired groups are attached onto the sidewall or tips of the CNTs permanently in an irreversible manner. Various chemical groups such as carboxylic, p-aminobenzoic acid, fluorine, added dichloro-carbon groups are attached to the surface or at the ends of the CNTs [85-88]. The advantages of chemical functionalization are that it can be attached covalently with polymeric materials and dispersed well in different solvents. The main disadvantage of the chemical function is the production of defects on CNTs. Various methods of the functionalization of CNTs are shown in Fig. 6.

4.3. Dispersion of CNTs using surfactants

The use of surfactants has also been reported for the purpose of CNT dispersion in polymeric materials [89]. Some important surfactants such as polyethylene glycol, sodium dodecyl
and for the creation of high-strength composites, fuel cells, ener-
tations that require conductivity and a high absorption capacity
of CNTs can be achieved through the use of CNTs for applica-
tions and the use of CNTs as fillers [92]. More attractive applications
of energy storage, with many studies focusing on nanotechnology
researchers have dedicated much effort to the creation of novel
materials come into use regularly, the potential of CNTs is most
promising. Since their discovery by Iijima [5] in 1991, CNTs are
the most rapidly growing nanomaterials in the field of nanotechnol-
ogy. Many researchers working in the field of nanocomposites
have attempted to use CNTs as a filler. The main idea for incor-
porating CNTs into different polymeric and other materials is
to improve the properties of these materials. By doing so, the
mechanical, electrical and thermal properties are improved to al-
most an ideal range. Garcia-Gutierrez et al. [96] prepared Melt-
processed injected molded polybutylene terephthalate (PBT)/
SWNTs nanocomposites and presented that SWNTs effect the
crystallization behavior of PBT. Soichia et al. [97] found that
the tensile modulus and yield strength increased with an addi-
tion of SWNT loading in a SWNTs/polyimide nanocomposite.
With good dispersion, they showed that the mechanical prop-
cies of polyimide were enhanced. Bhattacharyya et al. [98]
prepared melt-mixed styrene maleic anhydride (SMA) encap-
sulated SWNTs with a polyamide-12 (PA12) matrix in a coni-
cal twin-screw extruder. The process of encapsulation by the
SMA copolymer leads to a greater dispersion of SWNT and thus
enhances the interfacial adhesion between the PA12 and SMA-
modified SWNT. This leads to enhanced mechanical properties
of the formed product. Saeed and Park [99] prepared MWNT/
nylon nanocomposites by in situ bulk polymerization. They used
pristine MWNTs (P-MWNTs) and purified acid-treated MWNTs
(A-MWNT) as a reinforcing material and studied the mechanici-
thermal, electrical, and rheological properties as well as the
structural morphology and crystallization temperature via vari-
ounous techniques and compared the properties of both P-MWNT/
nylon and A-MWNT/nylon nanocomposites. It was concluded
that A-MWNTs can be well dispersed in nylon as compared to
P-MWNTs due to the presence of functional groups on the
A-MWNTs. The crystallization temperature increased with

gy conversion devices, field-emission devices, hydrogen storage
devices, and semiconductor devices [93,94]. Wastewater treat-
ment by CNTs is also a rapidly growing field for those who are
interested in adsorption studies [95]. The major problem associ-
ated with CNTs is their high cost and nonrenewable characteristic.
At present, special efforts are in progress to develop certain
preparation methods for CNTs which minimize their cost. Some
of the very important and promising applications of CNTs are
discussed below in detail.

5. Applications of CNTs

Nanotechnology is one of the latest and the most developed

tologies, presenting many advantages and benefits for new
materials with significantly improved properties. Nanotechnol-
ogy can be used in different applications in various fields, in-
cluding nano-medicine, energy, the environment, and in sensors
[91]. Although the fields of nanotechnology are vast and new
materials come into use regularly, the potential of CNTs is most
promising. Since their discovery by Iijima [5] in 1991, CNTs are
the most rapidly growing nanomaterials in the field of nanotechnol-
ogy due to their various applications. Many investigators and
researchers have dedicated much effort to the creation of novel
properties and to expanding the number of novel applications in
diverse fields, from materials science, medicine, electronics and
energy storage, with many studies focusing on nanotechnology
and the use of CNTs as fillers [92]. More attractive applications
of CNTs can be achieved through the use of CNTs for applica-
tions that require conductivity and a high absorption capacity
and for the creation of high-strength composites, fuel cells, ener-

Fig. 8. Functionalization of carbon nanotubes. Reprinted from Wu et al. [87] with permission from The Royal Society of Chemistry.

4.4. Physical dispersion by ultrasonication

Physical dispersion is also an important way to decrease the
agglomeration tendency of CNTs. Sonication provides certain
vibrational energies to agglomerated CNTs, overcoming the at-
ttractive forces within the nanomaterials and becoming dispersed
within a solvent or polymeric material. Fig. 8 shows different
approaches for the functionalization of CNTs.

5.1. CNTs as fillers

The use of CNTs as fillers in different materials to form nano-
composites is one of the most developed fields in nanotechnol-
ogy. Many researchers working in the field of nanocomposites
have attempted to use CNTs as a filler. The main idea for incor-
poring CNTs into different polymeric and other materials is
to improve the properties of these materials. By doing so, the
mechanical, electrical and thermal properties are improved to al-
most an ideal range. Garcia-Gutierrez et al. [96] prepared Melt-
processed injected molded polybutylene terephthalate (PBT)/
SWNTs nanocomposites and presented that SWNTs effect the
crystallization behavior of PBT. Soichia et al. [97] found that
the tensile modulus and yield strength increased with an addi-
tion of SWNT loading in a SWNTs/polyimide nanocomposite.
With good dispersion, they showed that the mechanical prop-
cies of polyimide were enhanced. Bhattacharyya et al. [98]
prepared melt-mixed styrene maleic anhydride (SMA) encap-
sulated SWNTs with a polyamide-12 (PA12) matrix in a coni-
cal twin-screw extruder. The process of encapsulation by the
SMA copolymer leads to a greater dispersion of SWNT and thus
enhances the interfacial adhesion between the PA12 and SMA-
modified SWNT. This leads to enhanced mechanical properties
of the formed product. Saeed and Park [99] prepared MWNT/
nylon nanocomposites by in situ bulk polymerization. They used
pristine MWNTs (P-MWNTs) and purified acid-treated MWNTs
(A-MWNT) as a reinforcing material and studied the mechanici-
thermal, electrical, and rheological properties as well as the
structural morphology and crystallization temperature via vari-
ounous techniques and compared the properties of both P-MWNT/
nylon and A-MWNT/nylon nanocomposites. It was concluded
that A-MWNTs can be well dispersed in nylon as compared to
P-MWNTs due to the presence of functional groups on the
A-MWNTs. The crystallization temperature increased with
an increase in the ratio of MWNTs in nylon. Prashantha et al. [100] prepared MWNTs and polypropylene (MWNT/PP) and MWNTs and polypropylene-grafted maleic anhydride (MWNT/PP-g-MA) nanocomposites and studied the rheological, mechanical, and morphological properties of these nanocomposites with various compositions of MWNTs using a range of techniques. They reported that MWNTs have better dispersion in PP-g-MA as compared to PP, and reported that MWNTs and PP-g-MA have good adhesion and strong interfacial strength as compared to MWNTs/PP because the MWNTs/PP-g-MA have high mechanical properties and an improved rheological percolation threshold. Zhang et al. [101] fabricated poly (adipic acid-hexamethylene diamine) (PA66) and F-MWNTs. Amino-MWNTs were used in the fabrication process, and the dispersion of A-MWNTs was increased in formic acid (HCOOH) after PA66 functionalization. The PA66 materials were grafted onto the surface of A-MWNTs. It was concluded that the chain length of the PA decreased with an addition of A-MWNTs, the thermal decomposition temperature of the PA-MWNTs were higher than that of the pure PA66 composite, and the storage modulus was improved with an addition of A-MWNTs.

5.2. In electronic devices as field-emission sources

CNTs can be used in electric devices as field-emission sources. This can be done when a potential is applied between the CNT surface and the anode. Electrons are easily emitted from their tips due to the curvature present in the CNTs in the form of pentagons [102,103] or due to the presence of oxidized tips [104,105]. With this principle, CNTs can be used for the fabrication of multiple electronic devices [104], including flat-panel displays, intense light sources, bright lamps [93,106,107], and X-ray sources [46,108]. Although CNTs are good emitters, nanocomposites of CNTs are also excellent electron-emission surfaces which are vacuum stable [109]. There are many advantages when using CNTs as an electron emitter. These include long lifetimes of the components, stable field-emission over prolonged time periods, low emission threshold potentials, the absence of the need for an ultra-high vacuum, and high current densities. It has been reported that large current densities as high as 4 A/cm² [107] can be achieved.

5.3. Batteries (Lithium ions batteries)

Lithium (Li) is a useful element, as it offers unique properties due to its lowest electronegativity and because electrons are easily donated from Li. Thus, it is the best candidate for the fabrication of lightweight and efficient batteries. However, despite the above advantages, the high reactivity of Li limits its applicability, as the metal loses its efficiency. This problem can be solved by the combining an application of CNTs and Li by intercalating Li ions within CNTs. This enables Li⁺ ions to migrate from a graphitic anode to the cathode. A separating medium is required between the anode and cathode, usually polyolefin. The theoretical Li storage capacity is expected to be 372 mAh/g when intercalated with CNTs. The charge and discharge phenomena in these batteries are controlled by the Li⁺ intercalation and de-intercalation rates [110,111]. Recently, Frackowiak and Beguin [112] showed that CNTs could be used in Li ion batteries. According to these authors, a high irreversible capacity is possible for CNTs. Meunier et al. [113] carried out calculations to determine the charging and discharging phenomenon in Li⁺ batteries. They suggested that by damaging the surface of the SWNT materials chemically or mechanically, one can increase the electrochemical storage of these batteries. On the basis of such possibilities, many electronics companies have begun to use carbon nanofibers and nanotubes as the electrodes in Li⁺ batteries to enhance their storage capacity and lifetimes.

5.4. CNTs in supercapacitors and actuators

Due to their large surface area as well as their high electrical conductivity, CNTs are excellent materials for use in electrochemical devices [107]. Niu et al. [114] and Ma et al. [115] were the first to demonstrate that with sheet electrodes of pyrolytically grown MWNTs, it is possible to achieve very high specific capacitances in individual cells in devices containing 38 wt% of H₂SO₄ as the electrolyte. The cells could reach power densities that exceeded 8,000 W/kg. Recently, a similar study was carried out by Frackowiak and Beguin [112] and Ma et al. [115], who demonstrated that MWNT-polypyrrole composites are able to reach specific capacitances of 163 F/g. CNT supercapacitors are used in applications to devices that require high power capabilities and higher storage capacities. The power densities approach 20 kW/kg at energy densities of 7 Wh/kg [112]. CNT-embedded supercapacitors can be used to provide fast acceleration and to store braking energy electrically for hybrid electric vehicles. Actuators are important devices, but the problem associated with them is that their efficiency decreases with an increase in the temperature. Therefore, CNT-modified actuators were prepared by several researchers. These work at relatively low voltages and at temperatures as high as 350°C [116]. For example, the maximum stress observed in SWNT actuators was 26 MPa [117]. This value is comparable to that of natural muscles, as it is 100 times larger than the value for natural muscle [103].

5.5. Sensors

Sensors are important detecting devices that are now widely used in different fields. The efficiency of biosensors and molecular sensors can be enhanced by attaching CNTs onto them. With chemical force microscopy techniques, Wong et al. [118] were the first to demonstrate that it is possible to sense functional chemical groups attached onto the ends of CNTs. Thus, it is possible to construct various types of sensors containing nanotube composite pellets, which are very sensitive to gases and which can be used to monitor leaks in chemical plants. Collins et al. [119] reported after working in a similar field that SWNTs are extremely sensitive to air and vacuum conditions by noting large variations in the electrical resistance levels of their SWNT samples. They also added that MWNTs can be used as efficient sensors for NH₃, H₂O, CO₂, and CO. Varghese et al. [120] detected changes in the resistance and capacitance levels of CNTs when the environment was slightly modified. In 2002, highly sensitive and fast-responsive microwave-resonant sensors were prepared for detecting NH₃ using either SWNTs or MWNTs [121]. In addition to gas sensing, CNTs and its composites can be used as
sensitive environmental pressure sensors [122]. Wood and Wagner noted that CNTs are very sensitive to liquid immersion or polymer-embedding processes, as the nanotubes slightly deform in the presence of different liquid media [123].

5.6. Gas and hydrogen storage

Due to their hollow cylindrical nature, CNTs can act as efficient gas and metal containers. It has been found that many important chemical species, such as metals, metal carbides, and oxides, can be introduced into CNT core by different methods, including (a) chemical treatments, arc-discharge methods, solid-state reactions and electrochemical techniques [124]. However, the major issues pertaining to these techniques are related to the fact that CNTs are not able to encapsulate gaseous substances. Recent studies have revealed that H₂ and Ar can be stored in SWNTs [125,126] and MWNTs [127], respectively. Terrones et al. [128] demonstrated experimentally that it is possible to introduce gaseous nitrogen inside MWNTs using a single-step process. They also reported that MWNTs can be loaded via the spray pyrolysis of ferrocene and benzyl amine solutions. Similar work was carried out by Trasobares et al. [129], but they used a powder pyrolysis of ferrocene and camphor under an ammonia atmosphere. The storage of different chemical species in CNTs may be advantageous for the fabrication of fuel cells for use mainly to power electric vehicles. Unfortunately, there is some controversy regarding the high-pressure storage of hydrogen. It is important to emphasize that the hydrogen storage capacity of CNTs ranges from 0.1 to 66 wt % [130,131]. Hirscher et al. [132] proved that the influence of impurities (coming from the CNT synthesis methods) may be responsible for reported previously results showing uptake levels as high as 7%. From a theoretical point of view, density functional theory has been used to calculate the H₂ storage capacity in CNTs. Different mechanisms by which CNTs possibly adsorb hydrogen molecules were proposed, including chemisorption, adsorption at interstitial sites, and the swelling of the nanotube array [133-135].

The above situations clearly show that CNTs may not be the best material for storing hydrogen, but additional experiments and further calculations should be carried out in order to clarify these results [136]. The adsorption of other gases such as He, NH₃, N₂, and SF₆ in CNTs as well as carbon foams, was recently achieved by Tanaka et al. [137].

5.7. Scanning probe tips

Scanning probe tips are of great importance as they can be used to obtain images with better resolutions. If a MWNT-bound scanning probe is used instead of a normal probe, it becomes possible to obtain a better image resolution as compared to earlier results [138]. Presently, Seiko Instruments and Daiken Chemical Company are attempting to commercialize these probes. Chemically modified nanotube tips can be used as sensors for detecting specific chemical and/or biological groups [125]. These sensors are important to detect added or even illegal substances. Kim and Lieber [139] determined experimentally that it is possible to fabricate nanotube tweezers by attaching two nanotubes onto a probe tip. This nano-tool operates according to the electrostatic interactions between two carbon cylinders. These achievements show clear advance regarding the use of nanotubes in current technologies, and it is clear that in the near future, further advances will be achieved.

5.8. Electronic devices using CNTs

CNTs are important nanomaterials that can be used in electronic devices to improve the properties of these devices. Tans et al. [38] fabricated a three-terminal switch-able device based upon SWNTs. The SWNT molecule was semiconducting and connected to metal nanoelectrodes. The performance at a low capacitance level was excellent. The major problem associated with nanotubes is the difficulty in manipulating them; thus, another method was devised to control the length and the electronic properties of individual nanotubes by STM nanostructuring [140]. Postma et al. [141] described that crossings and bends with SWNTs could be generated by means of AFM. This technique allows us to cut nanotubes into shorter sections using controlled voltages applied at the STM tips and to fabricate tiny nanotube devices that could be useful for the future construction of molecular machinery, nano-scale circuits and other nanoelectric materials [140,142]. There are many examples of experimental evidence indicating that CNTs can carry current densities of 10⁶ A/cm²; these values are much lower than those observed in metals (10⁹ A/cm²) [112]. Bachtold et al. [143] and Huang et al. [144] demonstrated for the very first time the fabrication of field-effect transistors that exhibit a high favorable gain, a large on-off ratio and room-temperature operation. The researchers showed that one-, two- and three-transistor circuits exhibit a range of digital logic operations. Examples include an inverter, a logic NOR, a static random-access memory cell, and an AC ring oscillator. A Harvard group in a similar way produced crossed nanowire p-n junctions and junction arrays that were configured as key OR and NOR logic-gate structures, showing substantial gain. They can be used for the development of novel computer technologies in the near future. Derycke et al. [145] demonstrated that CNTs can be used as a FET. The researchers also showed that pristine CNTs always behave as p-type transistors, whereas doped-nanotubes act as n-type devices. Both types could be integrated to fabricate voltage inverters [139]. Javey et al. [146] demonstrated that it is possible to generate logic rings as well as NOR and OR logic gates using arrays of p- and n-type nanotube FETs, as it is difficult to control the chirality of the tubes with the electronic properties. Collins et al. [147] demonstrated that it is possible to peel the outer layers of arc-discharged-produced MWNTs until the desired electronic properties of the outer shell are obtained. However, controlled growth in order to achieve selective chiralities needs to be investigated and exploited for more electrical applications. Blase et al. [148] also worked with a similar hypothesis and demonstrated that the electronic properties of CNTs can be utilized within polymeric materials to realize desired electrical applications.

5.9. Medical applications of CNTs

Given the increased profits associated with medical technology related to gene therapy, cancer treatments, and innovative new answers for life-threatening diseases, the science of nanomedicine has become the most rapidly growing field. The
unique properties and characteristics of CNTs enable scientists to develop new areas in nanomedicine. SWNTs and MWCNTs have already proven their potential to serve as safer and effective alternatives to previous drug delivery methods. They can pass through membranes, carrying therapeutic drugs, vaccines, and nucleic acids deep into the cell to the substrate targets. They serve as ideal non-toxic vehicles, which in some cases, increase the solubility of the drug, resulting in greater efficiency and safety. Overall, recent studies of CNTs have shown a very promising future for them in medicine [149].

6. Toxicity of CNTs and its control

Due to the extraordinary physical and chemical properties of CNTs, their usage in industry has been seriously considered, but there are certain problems associated with their use, especially problems related to their toxicity. CNTs can have adverse effects on human health, especially at the human pulmonary system, which is a primary route of exposure [150]. This is considerable concern among researchers at present regarding this [92,151-157]. Thus, certain steps are required to minimize the toxicity of CNTs. Over-exposure to CNT dust also causes inflammation and oxidative stress [158]. A recent study of CNTs showed that the length and rigidity of the nanotubes greatly influence the pro-inflammatory effect of CNT [159]. However, further research is needed to determine the possible influence of other physiochemical properties [160]. As their surface characteristics influence the pro-inflammatory effect of spherical nanoparticles [161], it can be expected that incorporating CNTs in polymeric materials will modify the surface properties of CNTs, which could modify their toxicity without affecting their specific properties and potential for use in future applications. The protective effect of the compatible solute Ectoine against CNT-induced lung inflammation has been studied recently [162]. However, a strategy based on the production of intrinsically safer nanomaterials seems to offer much more promise. Such approaches are essential for the further development and safe use of CNTs at the occupational level as well as at the level of the general user. From various studies of the toxicity of CNTs, it is clear that surface modifications are important to minimize CNT toxicity [163-167]. A coating could be a useful tool, as it allows modification of the external surface environment of CNTs without affecting their intrinsic structure or basic properties.

7. Conclusion

The synthesis, structure, physico-chemical properties as well as different applications of CNTs were reviewed in this paper. Important methods for the synthetic of CNTs (SWNTs and MWCNTs), including the arc-discharge method, laser ablation, CVD, and many other were discussed briefly. Some of the well-known properties of CNTs were also reviewed and presented and it was concluded that CNTs have a unique set of electrical, mechanical and thermal properties. Due to the greatest potentials of CNTs, it is clear that novel technologies will emerge in the near future, but the problem associated with these technologies is the quantity and cost of CNTs. Larger quantities of nanotubes are needed if composite materials are to be fabricated. It is highly likely that low-cost gas sensors, nanotube fabrics, novel catalytic supports, three-dimensional composite materials, heat exchangers, biological microfilters, and virus inhibitors will be produced using CNTs in the future. It was also reported that the nanotube functionalization methods which disperse CNTs well lead to less toxic CNTs than pristine CNTs.
